ABSTRACT

Context. Earth-like, extra-solar planets may soon become observable with upcoming high contrast polarimeters. Therefore, the characterization of the polarimetric properties of the planet Earth is important for the interpretation of expected observations and the planning of future instruments.

Aims. Benchmark values for the polarization signal of the integrated light from the planet Earth in broad band filters are derived from new polarimetric observations of the earthshine back-scattered from the Moon's dark side.

Methods. The fractional polarization of the earthshine p_{es} is measured in the B, V, R and I filters for Earth phase angles α between 30° and 110° with a new, specially designed wide field polarimeter. In the observations the light from the bright lunar crescent is blocked with focal plane masks. Because the entire Moon is imaged, the earthshine observations can be well corrected for the stray light from the bright lunar crescent and twilight. The phase dependence of p_{es} is fitted by a function $p_{es} = q_{max} \sin^2 \alpha$. Depending on wavelength λ and the lunar surface albedo a the polarization of the back-scattered earthshine is significantly reduced. To determine the polarization of the planet Earth we correct our earthshine measurements by a polarization efficiency function for the lunar surface $\epsilon(\lambda, a)$ derived from measurements of lunar samples from the literature.

Results. The polarization of the earthshine decreases towards longer wavelengths and is about a factor 1.3 lower for the higher albedo highlands. For mare regions the measured maximum polarization is about $q_{max,B} = 13\%$ for $\alpha = 90^\circ$ (half moon) in the B band. The resulting fractional polarizations for the planet Earth derived from our earthshine measurements and corrected by $\epsilon(\lambda, a)$ are 24.6 % for the B band, 19.1 % for the V band, 13.5 % for the R band, and 8.3 % for the I band. Together with literature values for the spectral reflectivity we obtain a contrast C_p between the polarized flux of the planet Earth and the (total) flux of the Sun with an uncertainty of less than 20 % and we find that the best phase to detect an Earth twin is around $\alpha = 65^\circ$.

Conclusions. The obtained results provide a multi-wavelengths and multi-phase set of benchmark values which are useful for the assessment of different instrument and observing strategies for future high contrast polarimetry of extra-solar planetary systems. The polarimetric models of Earth-like planets from Stam (2008) are in qualitative agreement with our results but there are also significant differences which might guide more detailed computations.

Key words. polarization – Earth – Moon – instrumentation: polarimeters – extra-solar planets – scattering

1. Introduction

This paper presents polarimetric observations of the earthshine on the Moon's dark side for a characterization of the integrated polarimetric properties of the planet Earth for the future investigation of Earth-like extra-solar planets.

With the rapid progress in observational techniques the detection of reflected light from terrestrial or even Earth-like extra-solar planets may become possible in the near future with high-contrast imaging of very nearby ($d \lesssim 5pc$) stars. Statistical studies based on the radial velocity survey of stellar reflex motions due to low mass planets (Mayor et al. 2011) or the planetary transit frequency of small planets by the KEPLER satellite (Howard et al. 2012) indicate both that terrestrial planets could be present with high probability around every nearby star. The detection of a periodic RV-signal in α Cen B by Dumusque et al. (2012), which was attributed to a planet with a mass of $\approx 1M_{Earth}$, demonstrates that the very nearest stars are really excellent targets for the search of extra-solar planets.

The intensity contrast between a reflecting planet and the parent star is

$$C_I(\alpha, \lambda) = f(\alpha, \lambda)(R_p/d_p)^2, \quad (1)$$

where α is the phase angle, R_p the radius of the planet, d_p its separation to the star, and $f(\alpha, \lambda)$ the phase dependent reflectivity. Thus the contrast is high for small separations d_p and therefore the prospect for direct detection is particularly favorable for close-in planets $d_p \lesssim 0.3$ AU around nearby stars for which such a small separation planet can still be spatially resolved. However, detecting a faint signal from a reflecting planet at an angular separation of about 0.1 arcsec from a bright star is challenging and requires an instrument with high spatial resolution and very high contrast capabilities based on coronagraphy and some kind of differential imaging. The upcoming planet finder instruments SPHERE (Beuzit et al. 2008) and GPI (Macintosh et al. 2012) will provide both much improved performance for substantial progress in this direction. A particularly promising technique for the search of reflected light from planets around the nearest stars is differential polarimetric imaging available with the SPHERE instrument. With sensitive polarimetry one can search for a polarized signal due to the scattered and therefore polarized light

from the planet in the halo of the unpolarized light from the star (e.g. Schmid et al. 2006). The measurable polarization contrast can be described similar to the intensity contrast by

$$C_p(\alpha, \lambda) = p(\alpha, \lambda) f(\alpha, \lambda) (R_p/d_p)^2, \quad (2)$$

where $p(\alpha, \lambda)$ is the integrated fractional polarization. Therefore, the investigation of $p(\alpha, \lambda)$ and the polarization flux $p(\alpha, \lambda) \times f(\alpha, \lambda)$ of planet Earth is important for the planing of future observing projects on extra-solar planetary systems and the interpretation of observational data. Up to now only very limited data are available for the integrated polarization of the planet Earth. The oldest and still best polarization phase curve of Earth originates from the observations of the earthshine by Dollfus (1957).

He determined the earthshine polarization phase curve $p_{es}(\alpha)$ with visual observations (i.e. in the V band) for Earth phase angles from $\alpha = 22^\circ$, about 1.5 days after new moon, to about $\alpha = 140^\circ$, between half and full moon. Dollfus (1957) finds for dark regions (maria) on the Moon a steady increase of the fractional polarization of the earthshine from about $p_{es} \approx 2\%$ around $\alpha = 30^\circ$, to a maximum polarization of about $p_{es} \approx 10\%$ for $\alpha \approx 100^\circ$, and a decline for larger α 's down to $p_{es} \approx 4\%$ at $\alpha \approx 140^\circ$. Dollfus (1957) also finds a higher fractional polarization for the back-scattered light for dark regions with surface albedo of about $a = 0.1$ than for bright regions with $a = 0.2$. In addition he notes a wavelength dependence in the fractional polarization of the earthshine with higher values at shorter wavelength. One should note that the back-scattering by the lunar surface introduces a depolarization of the earthshine. Thus, the fractional polarization of the light scattered by Earth is higher by a factor of about 2 to 3 than the measured value from the back-scattered earthshine.

Space experiments did not provide much progress because full Earth polarimetry was to our knowledge not taken or at least not published. Earth observing satellites with polarimetric capabilities took usually measurements of only small fractions of the Earth surface from which it is difficult to determine the net polarization for the entire planet. A result from the POLDER satellite was reported by Wolstencroft & Breon (2005) who obtained fractional polarization values for $\alpha = 90^\circ$ for three wavelengths and different cloud coverages. For a typical value for the average cloud coverage of 55% they derive for the polarization of the planet Earth: $p(443 \text{ nm}) = 22.6\%$, $p(670 \text{ nm}) = 8.6\%$, $p(865 \text{ nm}) = 7.3\%$.

An interesting new result on the Earth polarization from earthshine measurements is the VLT spectro-polarimetry from Sterzik et al. (2012) which show narrow spectral features due to water, O_2 , and O_3 absorptions in the Earth atmosphere and a rise of the fractional polarization towards the blue due to Rayleigh scattering.

Model calculations have been made for the fractional polarization of the reflected light from Earth-like planets (Stam 2008) as well as the polarization produced by reflecting clouds (e.g. Karalidi et al. 2011, 2012; Bailey 2007) or glint from ocean water surfaces (Williams & Gaidos 2008). The models provide an adequate description of the dominating scattering processes and the signatures of different surface types. However, the overall net polarization of Earth depends strongly on the not so well known contributions of the different areas to the total signal. Therefore it is very desirable to have better observational data which constrain between the various model options.

Lunar earthshine observations are very attractive for the investigation of the intensity and polarization of the reflected light of the Earth because they provide the integrated scattered light

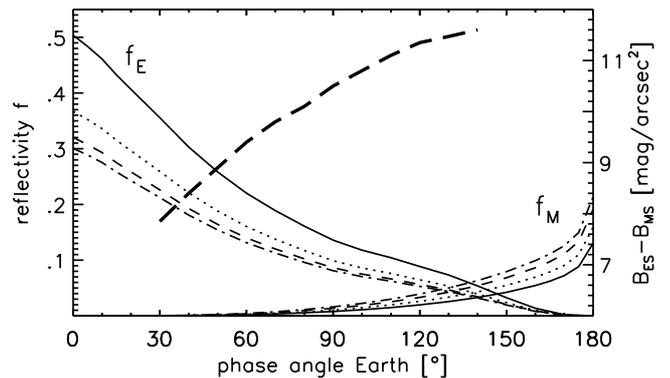

Fig. 1. Reflectivity of the Earth $f_E(\alpha_E, \lambda)$ and the Moon $f_M(\alpha_E, \lambda)$ for B (solid), V (dotted), R (dashed) and I (dash-dot). The thick dashed line is the difference of the surface brightness between earthshine $B_{es}(\alpha_E, \lambda)$ and moonshine $B_M(\alpha_E, \lambda)$ for the 400-700 nm pass band.

signal from the whole planet Earth from the ground. However, for the retrieval of the real level of scattered intensity f_E and fractional polarization p_E of the Earth from the measured earthshine signals f_{es} and p_{es} one needs also to consider the back-scattering properties of the absorbing and depolarizing lunar surface.

In addition, earthshine observations are very special because the Moon is a bright and large target for modern astronomical instrumentation and because the contrast between the bright crescent and the dark side of the Moon is very high. It is therefore not straightforward to disentangle the earthshine from the disturbing contributions of the variable atmospheric (and instrumental) stray light from the bright moonshine and of the twilight.

In this paper we describe new earthshine polarization measurements taken with an imaging polarimeter specially designed for earthshine observations. Our data cover Earth phase angles from 30° to 110° providing calibrated $p_{es}(\alpha)$ curves in the four broad-band filters B, V, R and I for lunar maria and highlands which are corrected for the stray light from the moonshine and the sky background. Section 2 describes our instrument and Sect. 3 our measurements while Sect. 4 discusses the data reduction. The observational results are given in Sect. 5 and then we discuss in Sect. 6 our correction for the depolarizing effect of the lunar surface. The final polarization phase curves $p_E(\alpha, \lambda)$ for Earth and the derivation of the polarization flux $p_E \times f_E$ and the Earth-Sun polarization contrast C_p are given in Sect. 7. The last Section 8 gives a summary and discusses the potential of earthshine polarization measurements.

2. Instrumentation

2.1. Instrument requirements

The (surface) brightness of the lunar earthshine, the moonshine, and the contrast between the bright and dark side of the Moon are described in the literature and summarized in Fig. 1. The reflectivity of the Moon $f_M(\alpha_M, \lambda)$ is from Kieffer & Stone (2005) and plotted as function of the phase angle of the Earth α_E using $\alpha_E = 180^\circ - \alpha_M$. The reflectivity of the Earth $f_E(\alpha_E, \lambda)$ is from earthshine observations and model calculations by Pallé et al. (2003) for the pass band 400-700 nm. Due to the lack of multi-color earthshine observations the same shape for the reflectivity phase curve given by Pallé et al. (2003) is adopted for all colors and the curves for the different bands are just scaled with the fac-

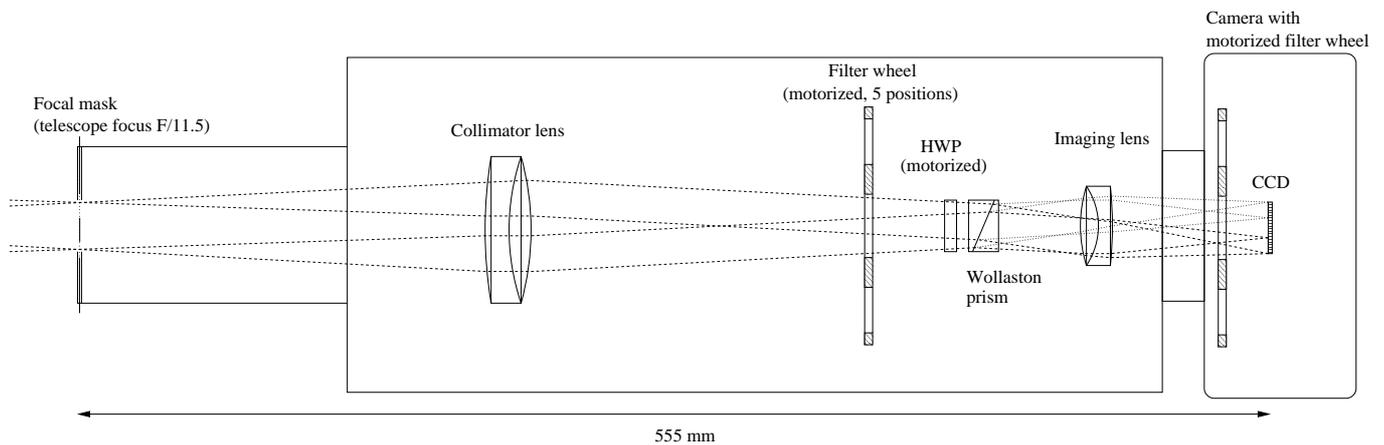

Fig. 2. Schematic overview of ESPOL with optical design and components drawn to scale. The focal mask is located in the focal plane of the 21cm telescope.

tors derived from earthshine spectra from Arnold et al. (2002) as described in Sect. 7.4. Measurements of the surface brightness of the earthshine $B_{es}(\alpha, \lambda)$ and the moonshine $B_M(\alpha, \lambda)$ were derived from observations of fiducial patches of highland regions (see also Qiu et al. 2003) by Montañés-Rodríguez et al. (2007) for the pass band 400-700 nm and Earth phase angles between $\alpha_E = 30^\circ - 140^\circ$. In Figure 1 we adopt their waxing Moon results and derive the mean daily surface brightness contrast $B_{es}(\lambda) - B_M(\lambda)$ (thick dashed line) between the dark and the bright side of the Moon. For $\alpha = 90^\circ$ (half moon) the surface brightness of the earthshine is $14.9 \text{ mag/arcsec}^2$. The difference between earthshine and moonshine ranges from 8 - 12 mag/arcsec^2 between $\alpha_E = 30^\circ - 140^\circ$.

The surface brightness of the earthshine is highest for the new moon phase and decreases with the Sun-Earth-Moon phase angle α (Fig. 1). Observations for small α near new moon require daytime or twilight observations for which a correction for the sky light is impossible or difficult. For $\alpha \approx 45^\circ$ an observational window of roughly 30 minutes with reasonably dark sky conditions becomes available after sunset or before sunrise for useful earthshine polarization measurements.

Observations during the night with much reduced sky background levels are possible for larger α , but the brightness of the moonshine due to the solar illumination increases rapidly (Fig. 1). At around $\alpha \approx 90^\circ$ the contrast between moonshine and earthshine becomes greater than about 10^4 and the light scattering in the Earth atmosphere and the instrument becomes more and more a problem for earthshine observations particularly in the red where the moonshine is strong and the earthshine weak. The light from the twilight sky and the moonshine are both strongly polarized $p > 3\%$ and this needs to be considered for an accurate measurement of the earthshine polarization. The polarization of the moonshine is discussed in detail in Sect. 5.3.

2.2. The earthshine polarimeter

The EarthShine POLarimeter (ESPOL) measuring concept takes the background and stray light conditions for earthshine observations into account. The instrument allows imaging polarimetry of the entire Moon and the surrounding sky regions in order to measure the polarization signal of the weak earthshine on top of the strong stray light from the moonshine and/or the light contribution from the sky. ESPOL includes in addition exchangeable focal plane masks to block the light from the bright moonshine.

The blocking of the bright crescent is required to allow for integrations of a few seconds without heavy detector saturation.

ESPOL is a dual-beam imaging linear polarimeter based on the rotating half-wave retarder plate and Wollaston polarization beam splitter concept. A schematic overview of the instrument is given in Fig. 2. The instrument includes a holder for exchangeable focal masks with different Moon phase shapes to block the light from the bright lunar crescent in order to avoid heavy detector saturation. ESPOL uses a super-achromatic $\lambda/2$ retarder plate on a motorized rotational stage for polarization beam switching and the selection of the Q and U polarization direction. The following Wollaston prism splits the light into the ordinary i_{\parallel} and extraordinary i_{\perp} beams with polarization perpendicular to each other. Both beams, each with a field of view of $50' \times 40'$ are imaged on the same 3072×2048 pixel CCD detector with a pixel scale of 1.5 arcsec/pixel . For our measurements we used a pixel binning of 3×3 pixels which reduced the spatial resolution to roughly 10 arcsec .

Color or neutral density filters with a diameter of 5 cm or 2 inches can be inserted into the five-position filter wheel located in the collimated beam or into the camera filter wheel respectively. In order to optimally align the focal masks to the orientation of the bright lunar crescent the mask holder can be rotated around the optical axis. In addition the whole instrument can be rotated around the optical axis to fix the zero-point of the polarization direction to any desired orientation.

ESPOL was built in-house for low costs using equipment for amateur astronomers and standard polarimetric and optical components for the wavelength range of 360-860 nm. The instrument is attached to an equatorially mounted 21 cm Dall-Kirkham Cassegrain telescope. As CCD system a thermo-electrically cooled SBIG-STL 6303E camera system with integrated filter wheel and shutter is used.

Figure 3 illustrates the data format delivered by the CCD. Due to the large field of view and the use of simple optical components the system shows quite some image distortion in north-south direction where the Moon diameter between ordinary and extraordinary beam differs by about 5%. These distortions can be tolerated because we are not interested in high spatial resolution but in the fractional polarization of extended surface regions.

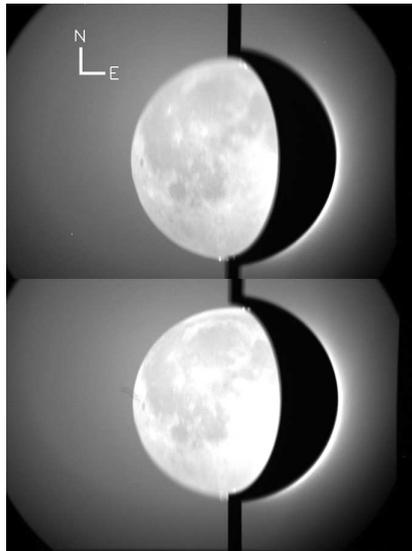

Fig. 3. ESPOL raw frame with the two polarization images i_{\parallel} and i_{\perp} of the earthshine on the Moon and the dark focal mask which blocks the light from the bright crescent.

3. Observations

With ESPOL we measured the polarization of the earthshine for different phase angles and different wavelengths using a Bessell B, V, R, I filter set (Bessell & Murphy 2012).

To minimize read-out overheads and detector noise the CCD was operated with 3×3 pixel binning providing a spatial resolution of about 10 arcsec, which is sufficiently high for distinguishing mare and highland regions on the Moon.

To minimize differential instrumental effects in the polarimetric signal the measurements were performed in beam-exchange mode (Tinbergen 1996). Only the linear Stokes components Q/I and U/I are measured.

One polarimetric cycle consists of two measurements with half-wave plate position 0° and 45° for Q/I and two measurements with position 22.5° and -22.5° for U/I . Typical integration times per exposure were about 2-10 s per half-wave plate position so that one full cycle could be recorded in about one minute. This is sufficiently fast to avoid problems with guiding drifts and strongly changing atmospheric conditions. To improve the S/N ratio typically a series of about 5 to 10 such datasets were recorded for each wavelength band during one observing night.

ESPOL was rotated for all our measurements, including standard stars, into the orientation of the plane Sun-Earth-Moon so that the Stokes $+Q$ direction is a polarization perpendicular to this plane and $-Q$ a polarization in this plane. The Stokes $\pm U$ directions are $\pm 45^\circ$ with respect to this plane. The alignment was done by eye by rotating the complete instrument until the crescent shaped focal mask completely blocked the moonlight which lead to an alignment accuracy of about $\Delta\theta = \pm 2^\circ$.

For instrument monitoring and calibration additional polarimetric measurements of the moonshine and polarized/unpolarized standard stars as well as darks and twilight flat-field calibrations were recorded during each observing night.

Our data were collected during two observing runs in March and October 2011. For the run in March the instrument was installed at the former Swiss Federal Observatory in Zurich at an altitude of 470 m above sea level. This run served mainly for first instrument testing and data with limited wavelength and phase coverage were obtained. Despite the non-optimal observing location in the heart of the city the data quality was good enough to be included in this study. For the second run we moved the instrument to the former Arosa Astrophysical Observatory at an altitude of 2050 m a.s.l. located in the Alps of eastern Switzerland.

Table 1. Observing log. The number of polarization cycles refer to the different filters taken for this date.

observing date	phase	filters	# pol. cycles
07.03.2011	31.5°	V	11
08.03.2011	42.5°	B, V, R	3, 9, 2
11.03.2011	75.5°	B, V, R	8, 19, 4
02.10.2011	73.0°	B, V, R, I	1, 3, 4, 4
03.10.2011	85.5°	B, V, R, I	5, 5, 4, 5
04.10.2011	98.0°	B, V, R, I	16, 15, 21, 6
05.10.2011	109.5°	B, V, R, I	8, 8, 10, 8

This site provides a much darker sky and a much reduced level of light scattering in the Earth atmosphere allowing measurements of the earthshine polarization for larger phase angles.

Both observing runs cover phase angles for the waxing Moon only. For the March measurements the earthshine originates mainly from the Atlantic Ocean, the Pacific Ocean, and the American continent while in October the earthshine was due to reflected light from South America and the Atlantic Ocean. Table 1 gives an overview of the observed phase angles of our measurements, the used filters and the number of polarization cycles for each filter.

4. Data reduction

4.1. Polarimetric reduction

Figure 3 shows a typical ESPOL raw frame with the ordinary i_{\parallel} and extraordinary i_{\perp} beams from the Wollaston showing the earthshine on the Moon in two opposite polarization directions. The bright crescent is blocked by the focal mask in order to suppress stray light in the instrument and to avoid disturbing detector saturation.

In the first data reduction step the raw images were dark subtracted before the two opposite polarization images i_{\parallel} and i_{\perp} for all half-wave plate orientations (0° , 45° , 22.5° and -22.5°) were cut out and aligned. Then the fractional Stokes parameter Q/I images were calculated according to the beam-exchange method described in Tinbergen (1996):

$$q = \frac{Q}{I} = \frac{R-1}{R+1} \quad \text{with} \quad R^2 = \frac{i_{0,\parallel}/i_{0,\perp}}{i_{45,\parallel}/i_{45,\perp}}, \quad (3)$$

where the first index of the image i refers to the $\lambda/2$ retarder orientation and \parallel and \perp indicate the two opposite polarization states from the ordinary and extraordinary beams of the Wollaston prism.

The corresponding intensity images are calculated by

$$I_Q = 0.5 \cdot (i_{0,\parallel} + i_{0,\perp} + i_{45,\parallel} + i_{45,\perp}). \quad (4)$$

The polarization and intensity images for the Stokes U measurements are determined in the same way but using the frames taken with $+22.5^\circ$ and -22.5° retarder positions.

In the differential polarization measurements effects like the spatial variations of the system throughput, detector pixel-to-pixel sensitivity differences and temporal changes between individual measurements are compensated to first order with the used double ratio, without any application of a flatfielding correction. Therefore, flatfielding was only applied on the intensity image I_Q described in Eq. (4) using an intensity flatfield image produced in the same way.

As described above there are some image distortions due to the large field of view and the relatively simple optical setup.

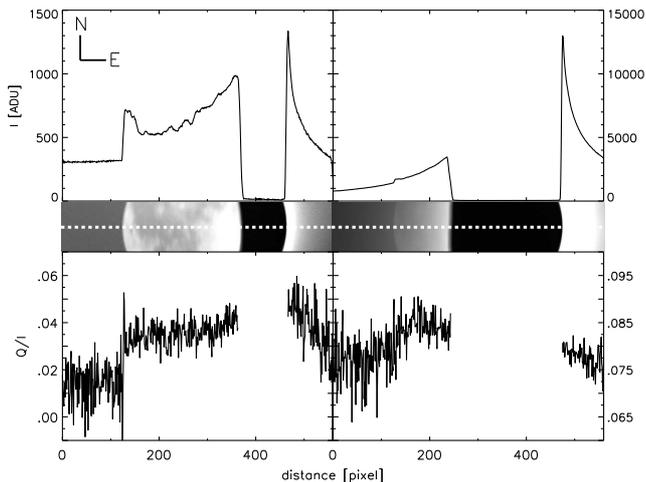

Fig. 4. Lunar west-east intensity (top) and polarization (bottom) profiles in the B band for phase 42.5° and 98.0° with low (left) and high (right) stray light contribution from the moonshine, respectively. The panel in the middle shows the corresponding stripe of the intensity images. The profiles were extracted from 10 pixel wide regions as indicated by the dashed lines in the middle panel.

These differential distortions between the ordinary i_{\parallel} and extraordinary i_{\perp} beams disappear almost entirely in the double ratio method because images from both beams are in the nominator and denominator of that ratio. This first order cancellation effect is not present in the summed intensity images and leads to some spatial smearing. Therefore the limb of the Moon is not sharp in the intensity image but on the more relevant larger scales, i.e. for the identification of extended mare or highland regions, the image distortions are negligible. Nonetheless we have considered in our data analysis that small scale features may be affected by image distortion effects and the associated alignment inaccuracies.

The polarimetric properties of ESPOL were tested with observations of zero polarization standard stars β Tau, β UMa, γ Boo, (Turnshek et al. 1990) and Vega (Bhatt & Manoj 2000) which show that the instrumental polarization is $\leq 0.5\%$ in all filters. From the polarized standard stars HD 21291, 9 Gem, ϕ Cas, 55 Cyg (Hsu & Breger 1982) we deduced a polarimetric efficiency above 98 % and checked the zero point of the polarization direction.

4.2. Extracting the earthshine polarization

We are interested in the measurement of the fractional polarization of the earthshine $(Q/I)_{\text{es}}$, which needs to be extracted from our data. Our observations show the contributions of three intensity components

$$I_{\text{tot}} = I_{\text{es}} + I_{\text{M}} + I_{\text{sky}}$$

from the earthshine (es), the scattered light from the moonshine (M) and the sky (see Fig. 4). In our images it is rather easy to distinguish these components, assuming that the sky is essentially constant over the whole field of view. The location of the earthshine is well defined and its intensity lies in a restricted range between the intensities of dark maria and bright highlands. The scattered light intensity from the moonshine has a more com-

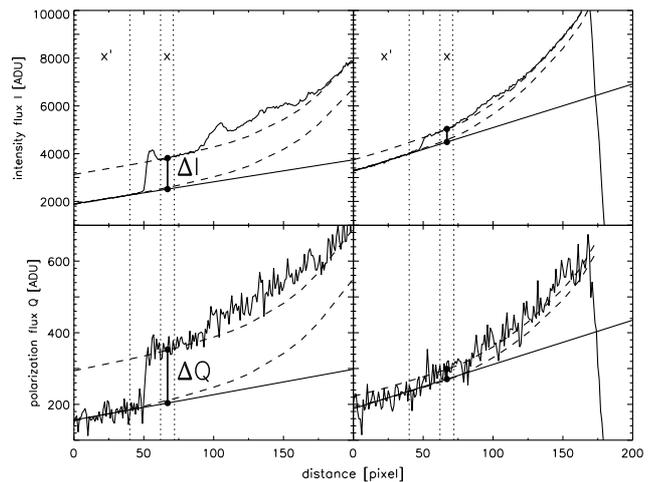

Fig. 5. Measuring the earthshine signals ΔI , ΔQ for relatively low (phase 73° , region #1, filter B) and high (phase 98° , region #1, filter R) moonshine levels with the background x' and measuring regions x indicated. The dashed lines illustrate the guessed level of the background (mainly stray light) and background plus constant earthshine regions (reflected from maria). The full line is the linear extrapolation of the measured background from the x' to the x region.

plex geometry. It is increasing rapidly towards the bright crescent which is covered in our data by the occulting mask.

The signatures of the three components can also be recognized in the fractional polarization W-E cuts extracted from the Q/I images shown in Figure 4. The B band observation for phase 42.5° shows a significant sky contribution from the twilight. The sky polarization is about 1.5 % on the west side of the Moon and the earthshine plus sky polarization is about 3.5 %. The polarization of the moonshine is slightly higher ($\sim 4.5\%$) as can be seen near the east side of the occulting mask where the scattered light of the moonshine dominates. For phase 98° the scattered moonshine with a polarization of about 8 % dominates strongly. The fractional polarization is just slightly enhanced at the position of the earthshine. The (Q/I) -images consist of the following contributions

$$\left(\frac{Q}{I}\right)_{\text{tot}} = \frac{Q_{\text{es}} + Q_{\text{M}} + Q_{\text{sky}}}{I_{\text{tot}}}. \quad (5)$$

Because of our definition of the $\pm Q$ -directions perpendicular and parallel to the scattering plane the U/I polarization is essentially zero ($\approx \pm 0.5\%$) and dominated by noise.

After some investigation we defined a procedure for the extraction of the fractional earthshine polarization $(Q/I)_{\text{es}}$ which provides also good results for large phase angles and the I filter for which the signal is weak and/or the stray light from the moonshine is very strong. For small phase angles the earthshine signal is strong and the measurement is easy. The basic idea is to measure the signal of the earthshine on top of the "background signal" in the I_{tot} frame and the Q frame where $Q = (Q/I)_{\text{tot}} \cdot I_{\text{tot}}$. The "background signals" (bg) are just the sum of the contributions of the sky and the moonshine $I_{\text{bg}} = I_{\text{sky}} + I_{\text{M}}$ and $Q_{\text{bg}} = Q_{\text{sky}} + Q_{\text{M}}$. For this we extract radial cuts and extrapolate the background signal from the region x' outside to a location x inside the lunar disk ($I_{\text{bg}}(x')$, $Q_{\text{bg}}(x') \rightarrow I_{\text{bg}}(x)$, $Q_{\text{bg}}(x)$) where

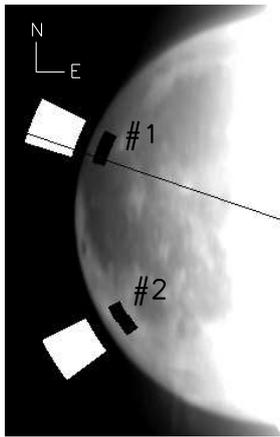

Fig. 6. Selected mare (#1) and highland (#2) fields used for the earthshine measurements together with their background regions (white areas).

we measure the earthshine + background level. The final signal is then:

$$\left(\frac{Q}{I}\right)_{\text{es}} = \frac{\Delta Q}{\Delta I} = \frac{Q_{\text{bg+es}}(x) - Q_{\text{bg}}(x)}{I_{\text{bg+es}}(x) - I_{\text{bg}}(x)}. \quad (6)$$

This procedure is illustrated in Figure 5, for two cases. The first is a strong and clear earthshine signal typical for phase angles $\alpha < 109^\circ$ in the B, V filters and phase angles $\alpha < 98^\circ$ in the R filter respectively. The large majority of our data are of this kind. The other case is typical for phase angles $\alpha \geq 98^\circ$ in the R and I band filter for which the stray light from the moonshine dominates strongly. The Q signal from the earthshine is still above but close to the measuring limit. Also given are fits to the background, which consists in these cases mainly of the moonshine plus a constant earthshine level fitted to the mare regions. The use of a linear extrapolation of the background in the x' region for the background correction of the total earthshine plus background signal measured at x seems reasonable (see also Qiu et al. 2003; Hamdani et al. 2006).

We have investigated more complex background/straylight correction procedures, e.g. using 3-parameter exponential fits, but they didn't agree better than the linear extrapolation. Important for the accuracy of the earthshine measuring process is the selection of areas close to the western limb but not exactly at the limb because image alignment uncertainties of the polarimetric data reduction can create disturbing spurious features at the limb. The limb is also not a good measuring region because of the extreme incidence and reflection angles (near 90°) with respect to the large scale surface normal which represents a situation which is not well explored for its back-scattering properties.

All our data show that the differences between the lunar dark mare and bright highland regions are significant when determining the intensity and polarization of the back-scattered earthshine. Therefore it is important to carry out separate measurements for these two main lunar surface types. Because of the strong albedo dependence (see Sect. 6) it is important that a chosen measurement field on the Moon does not have strong albedo variations. Under these terms we selected one mare field #1 in the Oceanus Procellarum area and one highland field #2 between Mare Humorum and the Moon's limb as indicated in Figure 6. Both fields are close to the western limb far away from the bright lunar side. They are available for measurements at all phase angles α taking into account increasing stray light and the lunar

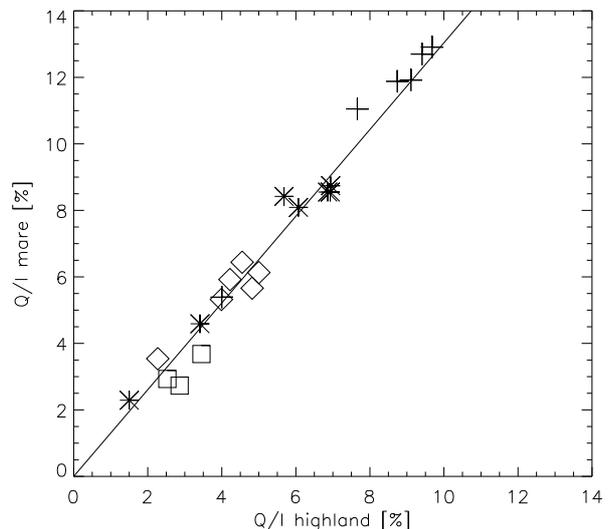

Fig. 8. Correlation between the fractional polarization for mare and highland regions measured simultaneously. The different symbols indicate the colors B(+), V(*), R(◇), and I(□). The line shows the derived proportionality factor 1.30 ± 0.01 .

libration. Therefore, for both fields a consistent data reduction could be carried out.

For both fields 10 radial I and Q profiles separated by one degree were extracted and ΔI and ΔQ was determined as described above. Table 2 gives the obtained $(Q/I)_{\text{es}}$ polarization values from both fields which are also plotted in Figure 7 as phase curves together with the statistical 1σ error bars Δ_{noise} .

As long as the S/N is sufficiently high the linear extrapolation method is robust. The total uncertainty for the obtained fractional polarization of the earthshine for a highland or mare region at a particular date can be described by the statistical noise plus a predominantly positive systematic offset $\Delta(Q/I)_{\text{es}} = \Delta_{\text{sys}} \pm \Delta_{\text{noise}}$.

The statistical 1σ uncertainty Δ_{noise} is small ($< 0.3\%$). This follows from the scatter of the obtained values from different extraction cuts of the same day and includes random noise, but also hard to quantify systematic effects due to small image drifts on the detector, changing stray light levels of the moonshine related to non-stable atmospheric conditions, and perhaps other unidentified effects.

For observations with very small earthshine signals (i.e. at large phase angles and/or strong stray light of the moonshine) the linear extrapolation of the background introduces a systematic overestimate Δ_{sys} of the result. This is because the moonshine dominated stray light background increases with an upward curvature towards the illuminated crescent. For the B, V, and R measurements at phase angles $< 100^\circ$ this offset is negligible or small ($< 0.5\%$). However in the I band filter at phase angle 109.5° the systematic offset is clearly dominating and the mare I band result for 109.5° is no longer useful (see Fig. 7). For this reason we disregard the mare I band result at 109.5° .

5. Earthshine polarization results

5.1. Data

The results for the fractional earthshine polarization Q/I measured in the Bessell B, V, R and I bands are presented in Table 2 and Figure 7. The plots in Fig. 7 also include the U/I data points

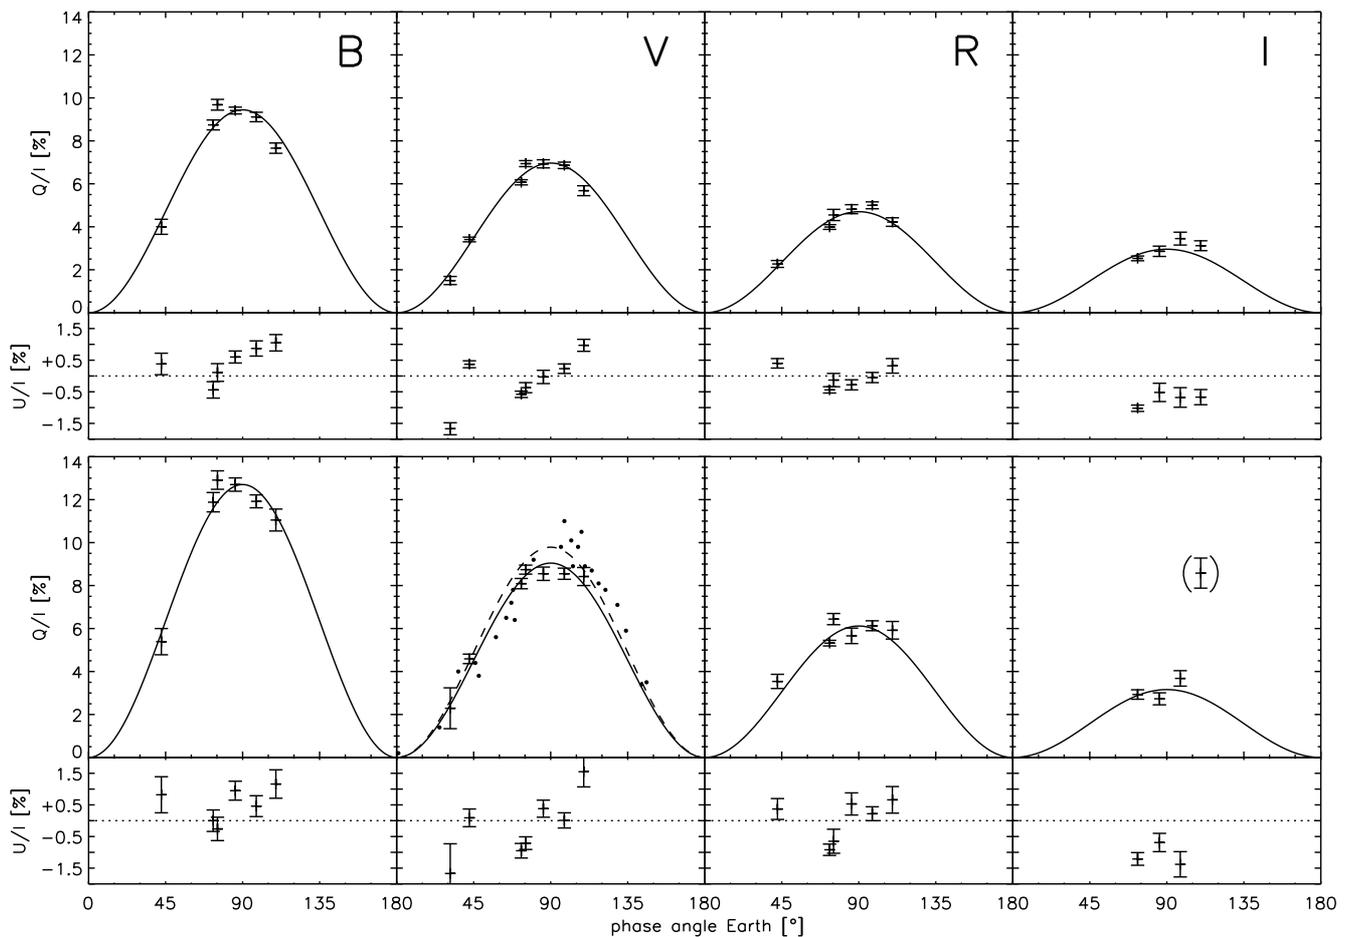

Fig. 7. Fractional polarization Q/I and U/I of the earthshine measured for highland (top) and mare regions (bottom) for the four different filters B, V, R and I (left to right). The solid curves are $q_{\max} \sin^2$ fits to the data. The error bars give the statistical 1σ noise Δ_{noise} of the data whereas the mare I band data at phase angle 109.5° are additionally affected by a substantial systematic offset $\Delta_{\text{syst}} > 0.5\%$. The dots in the V panel for the mare region indicate the measurements of Dollfus (1957) and a corresponding $q_{\max} \sin^2$ fit (dashed line) is also given.

and the estimated statistical 1σ uncertainties of the individual data points Δ_{noise} . The mare V band panel shows also the measurements by Dollfus (1957) which are in good agreement with our data.

Our earthshine data show a very good correlation between the polarization taken simultaneously for the highland and mare regions. Independent of color filter and phase angle the polarization for the mare region is a factor of 1.30 ± 0.01 higher than for the highland region as illustrated in Figure 8.

Good correlations are also found between different colors taken for the same observing date. When we plot the polarization $(Q/I)_{\text{es}}$ in the V, R and I band versus the polarization in the B band (Fig. 9) we find that the ratios are independent of α_E . We get the ratios 0.72 ± 0.02 , 0.49 ± 0.02 and 0.28 ± 0.05 for the ratios of the polarization between V and B band, R and B band, and I and B band respectively. Therefore, we conclude that to first order we can assume the same shape for the polarization phase curve for all wavelengths.

5.2. Fits for the phase dependence

The phase dependence of the earthshine polarization looks symmetric and can be well fitted with a simple $q_{\max} \sin^2(\alpha)$ curve. The model simulations by Stam (2008) for Earth-like planets

also support phase curves $q_{\max} \sin^p(\alpha)$. She calculates polarization phase curves assuming a range of surface types (e.g. forest-covered areas with Lambertian reflection, dark ocean with specular reflection) and cloud coverages. We find that the broad shape of her model phase curves can be well fitted by curves $\sim q_{\max} \sin^p(\alpha + \alpha_0)$ with $p \approx 1.5 - 3$ and $\alpha_0 \approx 0^\circ - 10^\circ$.

Furthermore, she finds characteristic features at low phase angles due to the rainbow effect and negative polarization at large phase angles due to second order scattering. We cannot assess the presence of such features because of the coarse phase sampling of our data.

Besides the $q_{\max} \sin^2(\alpha)$ curve we also tried functions with more free parameters to fit the data, e.g. using a curve like $q_{\max} \sin^p(\alpha + \alpha_0)$ and varying the exponent p between values of 1.5-3 and by introducing a phase shift α_0 . However, such fits provide not a significantly better match to the data. Because our data cover predominantly phase angles around quadrature the shape of the phase curve is not very well constrained.

The derived q_{\max} fit parameters for the different phase curves are given in Table 2 together with the standard deviation of the data points from the fit $\sigma_{\text{d-f}}$. For Q/I the typical $\sigma_{\text{d-f}}$ is $\approx 0.2\%$ in good agreement with the typical 1σ uncertainty of the individual data points Δ_{noise} . The standard deviation of the derived U/I values from the expected zero-value is only slightly higher and

Table 2. Fractional polarization values $(Q/I)_{\text{es}}$ for the earthshine from the mare and highland regions of all our measurements and corresponding typical statistical 1σ uncertainties Δ_{noise} . Also given is the fit parameter for $q_{\text{max}} \sin^2(\alpha)$ derived in Sect. 5.2 and the standard deviation of the data points from the fit $\sigma_{\text{d-f}}$. The polarization efficiencies $\epsilon_{\#1}$ and $\epsilon_{\#2}$ are derived in Sect. 6 and the depolarization corrected values $q_{\text{max,corr}}$ are given.

^avalue affected by systematic errors due to high stray light level (see text)

^bthe uncertainty of ϵ is mainly a systematic offset estimated to be $\Delta\epsilon = \pm 3\%$ (see text)

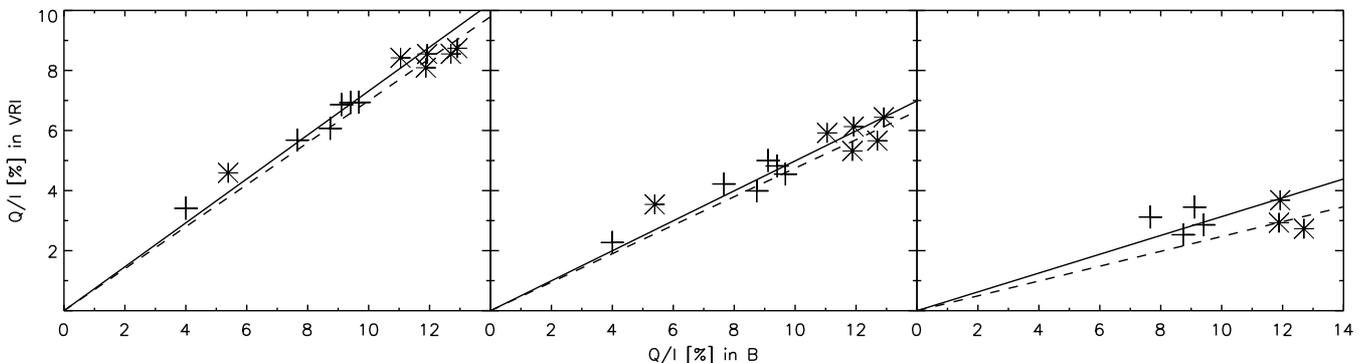

Fig. 9. Fractional polarization of the earthshine reflected at highland (+) and mare (*) regions in V, R and I band (left to right) with respect to the B band. The lines indicate linear fits both for highland (solid) and mare (dashed) data separately.

typically $\approx 0.3\%$ indicating that the instrument alignment with respect to the Sun-Earth-Moon plane was excellent (see Sect. 3). Note that the U signal is at the level of the measurement noise $|U| \approx \Delta_{\text{noise}}(U)$. Therefore one should not use the normalized total polarization $p = \sqrt{(Q/I)^2 + (U/I)^2}$ because the square in this formula introduces systematic errors. However, we estimate that the impact of U/I to the total polarization p is less than $\pm 0.05\%$. Therefore we use $p \approx Q/I$ and neglect the U component in the subsequent discussion.

5.3. The moonshine polarization

As a check of our polarimetry we can compare the polarization of the stray light from the moonshine with literature values from Coyne & Pellicori (1970) and Dollfus & Bowell (1971).

Forward scattering in the Earth atmosphere with scattering angles less than a few degrees does not introduce a significant polarization effect. Therefore, we can assume that the polarization of the lunar stray light $(Q/I)_{\text{M}}$ represents well the polarization of the bright lunar crescent. For areas just east of the Moon close to the focal mask (see Fig. 4) the scattered moonshine dominates strongly. There we can neglect the contribution of the sky background $(Q/I)_{\text{sky}}$ and assume that $(Q/I)_{\text{bg}} \approx (Q/I)_{\text{M}}$.

Figure 10 compares our results with the waxing Moon values given by Coyne & Pellicori (1970). They used different fil-

ters but their B' and G_{m} bands ($\lambda_{\text{eff}}[\mu\text{m}] = 0.45, 0.53$) are close to our B and V band respectively and the good agreement with our data underlines the consistency of our polarimetric data reduction.

Unfortunately Coyne & Pellicori (1970) used no red filters but the scaled G_{m} phase curve fits also well our R and I band data if scaling parameters of 0.80 and 0.65 are used respectively. This is in good agreement with the wavelength dependency of the maximum degree of polarization P_{max} of the whole Moon presented in Dollfus & Bowell (1971):

$$P_{\text{max},\lambda_1}/P_{\text{max},\lambda_0} = (\lambda_1/\lambda_0)^{-1.137}. \quad (7)$$

With this formula we obtain color ratios of $q(R)/q(G_{\text{m}}) = 0.81$ and $q(I)/q(G_{\text{m}}) = 0.64$ for the Moon polarization in good agreement with the above scaling parameters derived from our stray light data.

6. A correction for the depolarization due to the back-scattering from the lunar surface

The polarized light from the Earth is depolarized by the back-scattering from the particulate surface of the Moon. We express this effect as polarization efficiency ϵ , describing the fraction of linear polarization preserved. We simplify the treatment by considering only the Q linear polarization direction perpendicular

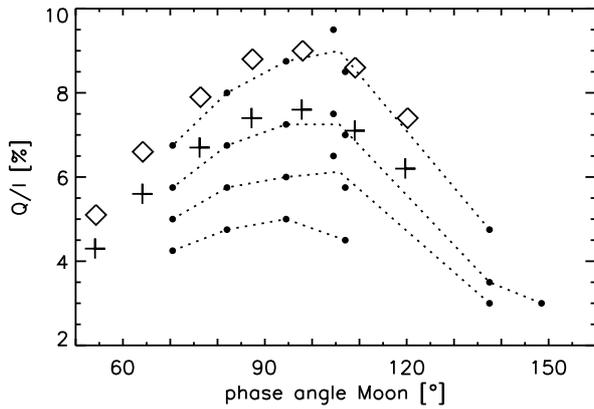

Fig. 10. Measured polarization of the lunar stray light near the focal mask in the B, V, R, and I filters (from top to bottom by filled dots and dashed lines). Also indicated are the polarization values given by Coyne & Pellicori (1970) for the disk integrated moonshine of the waxing Moon in their B' (\diamond) and G_m band (+).

and parallel to the scattering plane Sun-Earth-Moon. Then the polarization efficiency is

$$\epsilon = \frac{(Q/I)_{es}}{(Q/I)_E},$$

where $(Q/I)_E$ is the Earth polarization. The polarization efficiency $\epsilon(\lambda, a_i)$ depends on the wavelength and the surface albedo. We neglect the phase dependence in the back-scattering because the scattering angle is always $179^\circ \pm 0.5^\circ$.

The depolarization of the lunar surface was already investigated by Lyot (1929) and Dollfus (1957). They measured the depolarization of the back-scattering of volcanic ashes and fines, which were used as proxy for the lunar soil. They found a well defined anticorrelation between albedo and polarimetric efficiency.

Most important for the determination of $\epsilon(\lambda, a)$ are the albedo and polarization measurements for the reflection from several Apollo lunar soil samples by Hapke et al. (1993, 1998). They illuminated eight samples under an inclination of 5 degrees (to avoid specular reflection) with 100 % polarized blue and red light and measured the ratio of I_\perp/I_\parallel for phase angles 1° (\sim back-scattering) to 19° or scattering angles of 179° to 161° . The results for the linear polarization ratio are presented in Hapke et al. (1993) in graphical form and we extracted the data for phase angle 1° and derived the polarization efficiency ϵ . The normal albedos are only given for a phase angle of 5° (Hapke et al. 1993, Table 1) and we converted them into earthshine back-scattering albedos corresponding to 1° phase angle by applying a conversion factor of 1.25 ± 0.05 . We derived this factor from albedo phase curves presented in Velikodsky et al. (2011) where they give a comprehensive summary of the results of various independent photometric observations of the Moon including their own, Clementine data, and ROLO data.

The samples from Hapke et al. (1993) include 5 low albedo samples $a_{red} \approx 0.09 - 0.13$ representative for maria, 2 higher albedo samples $a_{red} \approx 0.15 - 0.19$ representative for highlands and one non-typical, extremely high albedo sample with normal albedo $a_{red} > 0.35$. This sample with NASA number 61221 was taken from white material at the bottom of a trench (see The Lunar Sample Compendium¹) and therefore we treat this sample as special case in our analysis.

¹ <http://curator.jsc.nasa.gov/lunar/compendium.cfm>

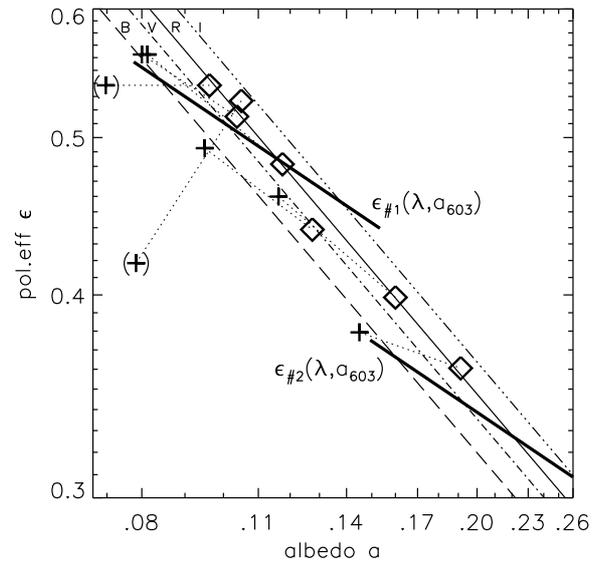

Fig. 11. Linear polarization efficiency as function of the normal albedo at 1° (Eq. 9) for the B (dashed), V (dash-dot), R (solid), and I (dash-dot-dot) band. More information about the fit procedure to the Hapke et al. (1993) samples in the red (\diamond) and the blue (+) is given in the text. Measurements of the same sample are connected by dotted lines. The thick black lines show the derived wavelength and albedo dependent polarization efficiencies for our two measurement areas #1 and #2 (Fig. 6).

Figure 11 shows the polarization efficiencies for the measurements of Hapke et al. (1993) as function of the 1° -albedo for a blue wavelength ($\lambda = 442$ nm) and a red wavelength ($\lambda = 633$ nm). The figure illustrates nicely the clear anticorrelation between albedo a and polarization efficiency ϵ .

We consider now in more detail the back-scattering properties of the lunar samples. All samples, except 61221, show a very similar color dependence in their albedo with $a_{red}/a_{blue} = 1.35$ ($\sigma = 0.05$). This is in agreement with the spectral variation of the mean lunar albedo \bar{a} from Dollfus & Bowell (1971) (see also Gehrels et al. 1964, Table XIII; and Velikodsky et al. 2011, Table 2) described by

$$\log \bar{a} = 0.83 \cdot \log \lambda[\mu\text{m}] - 0.80. \quad (8)$$

Inserting the wavelengths of the Hapke et al. (1993) measurements into this formula yields $\bar{a}_{red}/\bar{a}_{blue} = 0.108/0.0805 = 1.34$ in very good agreement with the above derived albedo ratio for the lunar samples.

For most samples the polarization efficiency is slightly higher (in one case equal) in the blue than in the red. There is one notable exception which is sample number 79221. Although the albedo of sample 79221 is lower in the blue than in the red its polarization efficiency is not higher as in all other samples. Also when looking into reflectivity studies for this sample (e.g. Noble et al. 2001) it is not clear why this sample could behave different in its depolarization properties than other maria soils. Therefore, we treat sample 79221 as an exception.

If we disregard sample 79221, then the remaining 6 samples have an average color dependence for their polarization efficiency ratio of $\epsilon_{red}/\epsilon_{blue} = 0.91$ ($\sigma = 0.05$). Including sample 79221 gives a mean ratio of 0.96 but a standard deviation which is with 0.14 significantly higher.

Based on these back-scattering measurements of lunar samples we derive a two dimensional linear fit for the polarization

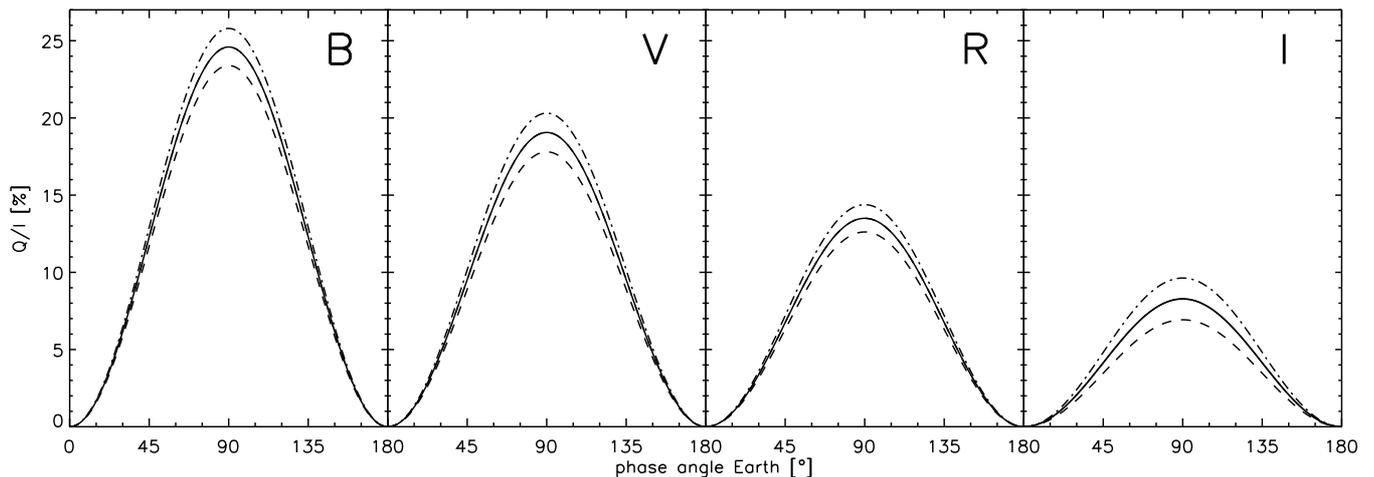

Fig. 12. Depolarization corrected polarization phase curves of Earth in the B, V, R, and I bands. The solid line indicates the mean of the mare (dashed) and highland (dash-dot) results based on the polarization efficiency correction derived in this work.

efficiency $\log \epsilon$ as function of $\log a_{603}$, the albedo at 603 nm, and $\log \lambda$ for the wavelength

$$\log \epsilon(\lambda, a_{603}) = -0.61 \log a_{603} - 0.291 \log \lambda [\mu\text{m}] - 0.955. \quad (9)$$

For this fit the wavelength dependence of the albedo has been assumed to be according to Eq. 8 and it was normalized to 603 nm. By fitting the red data points we find the logarithmic slope -0.61 ± 0.04 between the polarization efficiency ϵ and the albedo a_{red} which we also adopt for the blue data points. Finally, by fitting over the red and blue points separately we determine the other two parameters -0.291 and -0.955 . The resulting relation for the linear polarization efficiency as function of the normal albedo at 1° is shown in Fig. 11 for the B, V, R, and I band.

For the derivation of the albedos of our measurement regions we used the results of Velikodsky et al. (2011) who present maps of lunar apparent and equigonal albedos at phase angles $1.7^\circ - 73^\circ$ at wavelength 603 nm. We extrapolated their results to a phase angle of 1° and we get albedos $a_{\#1}(603 \text{ nm}) = 0.11 \pm 0.01$ and $a_{\#2}(603 \text{ nm}) = 0.21 \pm 0.01$. The resulting polarization efficiencies $\epsilon_{\#1}(\lambda, a_{603})$ and $\epsilon_{\#2}(\lambda, a_{603})$ are listed in Table 2 for the B, V, R, and I band and shown in Figure 11 giving the $\epsilon(\lambda, a_{603})$ fits. Overall we estimate the uncertainty of the derived polarization efficiency to be in the order of $\Delta\epsilon \approx \pm 3\%$.

The main uncertainty of this derivation stems from the uncertainty in the above mentioned albedo conversion from $\alpha = 5^\circ$ into albedos corresponding to 1° phase angle where the conversion factor 1.25 ± 0.05 leads to an uncertainty of the polarization efficiency of about $\Delta\epsilon = \pm 1.5\%$. To significantly improve the determination of ϵ accurate lunar albedo maps for back-scattering geometry are required. This is because for back-scattering at $\approx 1^\circ$ reflection is strongly influenced by the opposition effect of the lunar surface, i.e. a steep brightness surge due to coherent backscattering and shadow-hiding (e.g. Shkuratov et al. 2011 and references therein). In addition to that the Hapke et al. (1993, 1998) sample might not be representative for the surface properties of the Moon.

The logarithmic slope -0.61 ± 0.04 is better constraint for the low albedo samples and it introduces an uncertainty $\Delta\epsilon = \pm 1\%$ towards the higher albedo samples. Moreover, the logarithmic relation might not be valid over the complete albedo range between $a_\lambda = 0.09 - 0.19$ and two slopes, one for the maria and one for the highlands, might be necessary. However, based on

the available samples this is not obvious and one log fit may not be the best representation of the data. More direct measurements of the polarization efficiency of the lunar back-scattering are required to reduce this source of uncertainty.

7. Polarization of planet Earth

7.1. Fractional polarization derived from the earthshine

In Figure 12 we present the depolarization-corrected polarization phase curves of planet Earth in the B, V, R, and I bands and the corresponding corrected fit parameters $q_{\text{max,corr}}$ are listed in Table 2. For the B band we obtain a maximum polarization of about 25 % which decreases with wavelength to about 8 % in the I band. For perfect measurements and perfect polarization efficiency corrections the same Earth polarization $q_{\text{max,corr}}$ values should be obtained for the mare and highland regions. We note that the corrected highland results are systematically higher than the mare results by a factor of about 1.1 for the B, V, R bands and 1.4 for the I band. This reflects also the uncertainty in our determination of the polarization efficiency of the back-scattering $\Delta\epsilon \approx \pm 3\%$ derived in Section 6.

7.2. Comparison with previous measurements

In Fig. 7 we compare our earthshine measurements with the pioneering study of Dollfus (1957), who obtained his data with visual observations using a “fringed-field polariscope”. The agreement with our V band phase curve for the mare region is excellent. If we apply $q_{\text{max}} \sin^2$ fits (see Sect. 5.2) to both data sets the quadrature signals only differ by 0.8 %. The small deviations between Dollfus (1957) and us can be explained by different mare regions observed and the expectedly non-equal effective wavelengths of the two completely different types of measurements. For one night at $\alpha \approx 100^\circ$ Dollfus (1957) reports also the earthshine polarization in two filters, namely $p = 5.4\%$ for $0.55 \mu\text{m}$ (V' band) and 3.5% for $0.63 \mu\text{m}$ (R' band). The ratio $p_{V'}/p_{R'} = 1.54$ is again in excellent agreement with our polarization ratio $q_{\text{max,V}}/q_{\text{max,R}} = 1.47$. This indicates that the filters used by Dollfus (1957) must match quite well our filter pass bands.

The spectral dependence of the earthshine polarization observed with a spectral resolution of 3 nm was recently published by Sterzik et al. (2012). These sensitive spectro-polarimetric

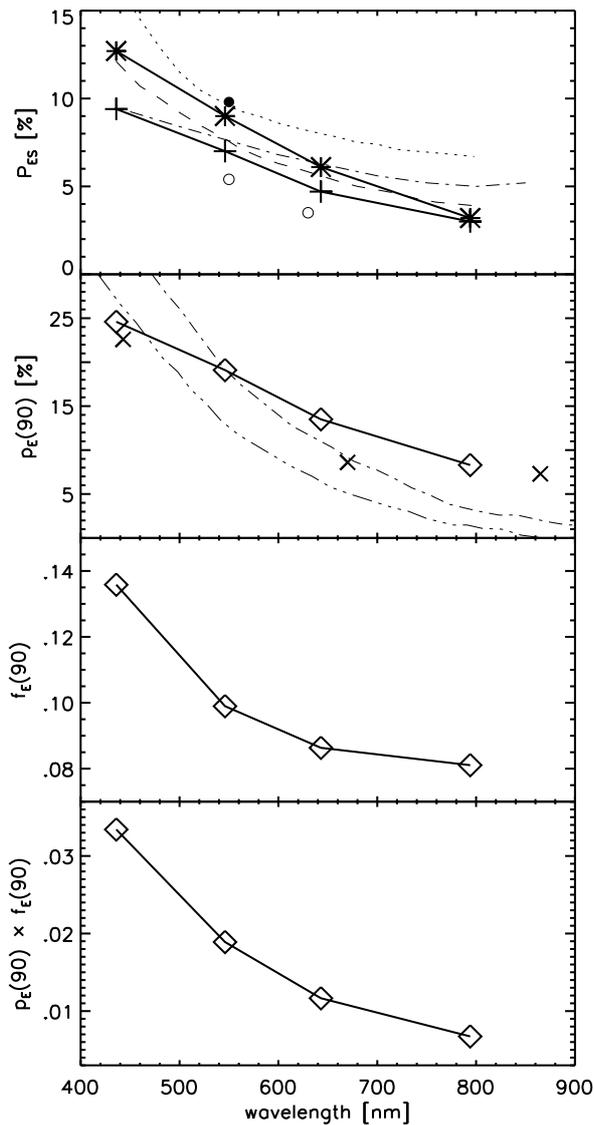

Fig. 13. Top: Earthshine polarization results at quadrature for maria (*) and highlands (+). The thin lines give the Sterzik et al. (2012) spectro-polarimetry for waning (dashed) and waxing (dotted) moon at Earth phases 87° and 102° respectively and the Takahashi et al. (2013) spectro-polarimetry (dash-dot) at 96° . The circles are the Dollfus (1957) values q_{\max} from Fig. 7 (filled) and two additional observations at Earth phase $\approx 100^\circ$ (open). 2nd panel: Earth polarization p_E from Table 3 (\diamond) compared to the POLDER/ADEOS results of Wolstencroft & Breon (2005) (\times) and two Stam (2008) models with 40 % (dash-dot) and 60 % (dash-dot-dot) cloud coverage. Bottom two panels: spectral reflectivity of Earth f_E and polarized reflectivity of Earth $p_E \times f_E$.

data reveal weak, narrow features of the planet Earth due to O_2 and H_2O on a smooth polarization spectrum decreasing steadily from the blue towards longer wavelengths. They present measurements for two epochs with phase angles $\alpha = 87^\circ$ for a waning moon phase and $\alpha = 102^\circ$ for the waxing moon phase. For the waning moon case they obtained an earthshine polarization of about $p_B = 12.1\%$ in the B band, $p_V = 7.7\%$ in V, $p_R = 5.6\%$ in R, and $p_I = 3.9\%$ in I, and a significantly higher polarization for the waxing moon phase with $p_B = 16.6\%$, $p_V = 9.7\%$, $p_R = 8.0\%$, $p_I = 6.7\%$ as plotted in Fig. 13.

Unfortunately it is not clear whether they measured the back-scattering from maria or highlands. Sterzik et al. (2012) attribute the polarization differences between the two epochs mainly to intrinsic differences of the polarization of Earth because the earthshine stems from different surface areas and were taken for days with different cloud coverage. Considering our polarization values for highlands and maria then it could be possible that the differences measured by Sterzik et al. (2012) are at least partly due to the mare/highland depolarization difference (or surface albedo difference).

Another spectra-polarimetric observation of the earthshine was published by Takahashi et al. (2013). They also find a rise of the fractional polarization of the earthshine towards the blue but with a much flatter slope. Unfortunately they do not report whether their results were obtained from maria or highlands either. Therefore, only a qualitative comparison with our data can be made. The observations of Takahashi et al. (2013) are conducted at 5 consecutive nights and cover phase angles $\alpha = 49^\circ - 96^\circ$. In the blue they find that the maximum polarization is reached at $\alpha \approx 90^\circ$. However, for wavelengths > 600 nm the polarization keeps increasing up to and including their last measurement at $\alpha = 96^\circ$. They conclude that the phase with the highest fractional polarization α_{\max} is shifted towards larger phase angles which could be explained by an increasing contribution of the Earth surface reflection. In our data we do not see this shift but neither can we exclude it because we were not able to derive meaningful data due to the very strong stray light from the moonshine and the weak signal from the earthshine. In this regime our linear extrapolation method to subtract the background stray light from the earthshine signal introduces a strong systematic overestimate Δ_{sys} of the result (see Sect. 4.2). Takahashi et al. (2013) also use a linear extrapolation method to determine the earthshine polarization but unfortunately they do not describe their data reduction in detail. Therefore, considering the limitations of our linear extrapolation, it could be possible that the shift of α_{\max} reported by Takahashi et al. (2013) is due to the strong stray light at phase angles $> 90^\circ$.

Overall, the spectral dependence of the polarization of Sterzik et al. (2012) and Takahashi et al. (2013) is qualitatively similar to our measurements but the level and slope of the fractional polarization differ quantitatively. Because Sterzik et al. (2012) and Takahashi et al. (2013) provide no information about the lunar surface albedo for their measuring area and do not assess the stray light effects from the bright moonshine their results cannot be used for a quantitative test of our results. The spectral slope of Sterzik et al. (2012) is slightly steeper than ours while the slope of Takahashi et al. (2013) is slightly flatter.

For an assessment of the polarization efficiency for the lunar back-scattering we used literature data for polarimetric measurements of lunar samples by Hapke et al. (1993, 1998) and we derive a wavelength and surface albedo dependent polarization efficiency relation $\epsilon(\lambda, a_{603})$ which gives for mare in the V band $\epsilon(V, 0.11) = 50.8\%$. This value is significantly higher than the 33 % derived by Dollfus (1957) which he based on the analysis of volcanic samples from Earth used as a proxy for the lunar maria. Because of this, the Earth polarization derived in this work is much lower than the value given in Dollfus (1957). We are not aware of other studies on the polarization efficiency ϵ for the lunar back-scattering. Relying the determination of ϵ on real lunar soil is certainly an important step in the right direction for a more accurate determination of the polarization of Earth.

Very valuable are the reported Earth polarization values from Wolstencroft & Breon (2005) based on direct polarization measurements with the POLDER instrument on the ADEOS satel-

Table 3. Geometric albedo A_g , phase integral A_s/A_g and quadrature results for the planet Earth. Given are the fractional polarization p_E , the Earth reflectivity f_E , the polarized reflectivity $p_E \times f_E$, and the polarization contrast $C_p = p_E \times f_E \times (R_E/d_{S-E})^2$ for an Earth-Sun system. The systematic offset uncertainty Δp_E is due to the uncertainty of the depolarization and albedo of the lunar surface.

¹Cox (2000)

lite. They derived the fractional polarization for the wavelengths 443 nm (B'), 670 nm (R') and 865 nm (I') for different surface types and cloud coverage. Weighted mean values representative for an integrated planet Earth observation (55 % cloud coverage) of 22.6 %, 8.6 % and 7.3 % in the B', R' and I' band are obtained which are also indicated in the second panel of Fig. 13. The good agreement between our derivation based on the earthshine and the values from Wolstencroft & Breon (2005) confirms our determination of the polarization efficiency. Unfortunately, it is not possible to assess whether the R band point of this study differs significantly from the value of Wolstencroft & Breon (2005) because they give no description of their data and uncertainties.

7.3. Comparison with the models from Stam (2008)

The study of Stam (2008) is unique for the modeling of the spectral dependence of the fractional polarization of Earth-like planets. In her work she explored also dependencies on a range of physical properties different from Earth. For our comparison we pick the model for an inhomogeneous Earth-like planet with 70 % of the surface covered by a specular reflecting ocean and 30 % by deciduous forrest (lambertian reflector with an albedo for forest), and cloud coverages 40 % and 60 %. When compared to our Earth polarization determinations (Fig. 13, second panel), these models agree with our measurements at short wavelengths but show a clear deficit in the fractional polarization at long wavelengths in the I band. This is not surprising since the models were not tuned to the case of Earth. In the models only very thick, liquid water clouds were included but no thin liquid water clouds and no ice clouds. Karalidi et al. (2012) showed that with more realistic cloud properties for Earth the degree of polarization can vary strongly depending on cloud optical thickness. Hence, our data could now be used to test and to improve model calculations for the Earth polarization.

7.4. Polarization flux contrast for the Earth - Sun system

A key parameter for the polarimetric search and characterization of Earth-like extra-solar planets is the polarization flux $p \times f$ of a planet or the polarization flux contrast C_p as described in Eq. 2. The polarization flux of a highly polarized planet is easier to measure than the fractional polarization p , because the reflected intensity cannot be distinguished easily from the scattered light halo of the central star in high contrast observations. But because

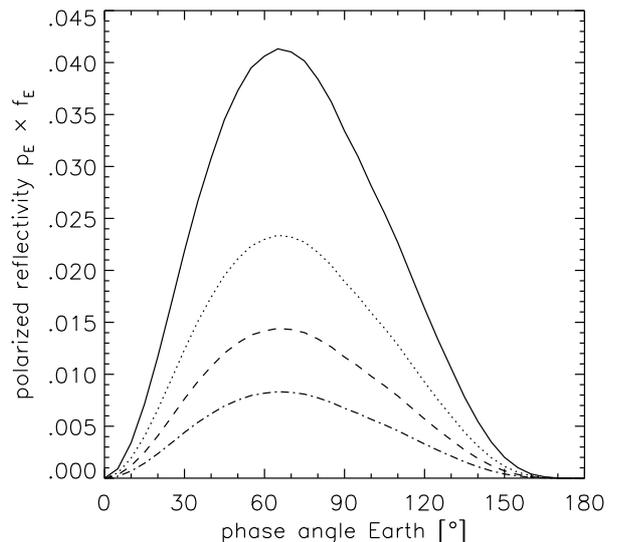

Fig. 14. Polarized reflectivity phase curve $p_E(\alpha) \times f_E(\alpha)$ for Earth in the B (solid), V (dotted), R (dashed), and I band (dash-dot).

stars are essentially unpolarized, it should be possible to detect a differential signal of polarized light from extra-solar planets with high contrast polarimetric imagers as foreseen for the upcoming instrument SPHERE/VLT and planned for future facilities like the E-ELT (e.g. Schmid et al. 2006; Beuzit et al. 2008; Kasper et al. 2010). The polarimetric detection of an Earth-like planet is difficult but, nonetheless, it is useful to have accurate values for the expected signal for the planning of such observations.

The prediction of the polarization flux of an exo-Earth requires besides the fractional polarization $p(\alpha, \lambda)$ determined in this work also the reflected intensity $f(\alpha, \lambda)$.

The reflected intensity of Earth can be split into a wavelength dependent geometric albedo term $A_g(\lambda) = f(0^\circ, \lambda)$ and a normalized phase dependence $\Phi(\alpha)/\Phi_0$ where $\Phi_0 = \Phi(\alpha = 0)$ according to:

$$f(\alpha, \lambda) = A_g(\lambda) \frac{\Phi(\alpha)}{\Phi_0}.$$

With this approach we neglect the color dependence of the phase curve, which is not known but certainly small when compared to the measuring uncertainties for the spectral albedo $A_g(\lambda)$ and the uncertainties in the fractional polarization $p_E(\lambda, \alpha)$.

The visual geometric albedo of Earth is $A_g(V) = 0.367$ (Cox 2000). With the relative spectral reflectance measured by Arnold et al. (2002), Woolf et al. (2002) and Montañés-Rodríguez et al. (2005), we deduce the geometric albedo for the individual B, V, R, and I filters as given in Table 3.

For the phase dependence $\Phi(\alpha)/\Phi_0$ we use the phase curve determined by Pallé et al. (2003) for the 400-700 nm filter normalized to the B, V, R, and I band geometric albedos derived above. The derived phase curves are given in Fig. 1 and their value for $\Phi(90^\circ)/\Phi_0 = 0.27$ yields the polarized reflectivity for quadrature phase $p_E(90^\circ) \times f_E(90^\circ)$ for the B, V, R, and I filters as plotted in Fig. 13 and given in Table 3.

The phase curve f_E of Pallé et al. (2003) is based on earthshine measurements at phases between $\alpha = 30^\circ - 145^\circ$ extrapolated to $\alpha = 0^\circ - 180^\circ$. This broad phase angle coverage is unique and remains, to our knowledge, the only available observation of the phase dependence $\Phi(\alpha)$ of f_E . For future reference we also give in Table 3 the phase integral parameter A_s/A_g , the

ratio between spherical and geometric albedo, derived from the Pallé et al. (2003) data.

The spectral dependence of the polarization flux $p_E(\lambda, 90^\circ) \times f_E(\lambda, 90^\circ)$ of Earth decreases steeply towards longer wavelength, because both, the fractional polarization p_E and the reflectivity f_E are higher for the blue than the red. The $p_E \times f_E$ signal in the B band is about a factor 5 times stronger than in the I band.

The polarization contrast $C_p(\lambda, 90^\circ)$ according to Eq. 2 is determined from $p_E \times f_E$ and using R_E^2/AU^2 . This yields values at the level of a few times 10^{-11} only (Table 3). One should note that an Earth-like planet in the habitable zone of a M star with $L = 0.02 L_\odot$ is at a much smaller separation of 0.14 AU. In this case the expected polarization contrast is about a factor of 50 higher and within reach for a high contrast imaging polarimeter at an ELT (Kasper et al. 2010).

The B, V, R, and I phase curves for the polarized reflectivity $p_E \times f_E$ are plotted in Fig. 14. The maximum signal occurs near $\alpha \approx 65^\circ$, which is thus the best phase for a detection.

8. Summary and Discussion

This work presents measurements of the earthshine polarization in the B, V, R and I bands. The data were acquired with a specially designed wide field imaging polarimeter using a focal plane mask for the suppression of the light from the bright lunar crescent. Thanks to this measuring method we can accurately correct for contributions from the (twilight) sky and the scattered light from the bright lunar crescent and derive values with well understood uncertainties. We derive phase curves for the fractional polarization for the earthshine reflected from maria and highlands for the different filter bands. The phase curves can be fit with the sine-square function $q_{\max} \sin^2(\alpha)$. The amplitude q_{\max} decreases strongly with wavelength from about 13 % in the B band to about 3 % in the I band (see Table 2). The fractional polarization of the earthshine is about a factor 1.3 higher for the dark mare region when compared to the bright highland. Our phase curve for the mare region in the V band is in very good agreement with the historic visual polarization phase curve from Dollfus (1957).

We study the depolarization introduced by the back-scattering from the lunar surface based on published polarimetric measurements of lunar samples (Hapke et al. 1993, 1998). We derive a 2-dimensional fit function for the polarization efficiency $\epsilon(\lambda, a_{603})$ for the back-scattering which depends on wavelength and surface albedo. Earthshine measurements plus ϵ correction yield as main result of this paper the fractional polarization of the reflected light from the planet Earth as function of phase in four bands. The polarization of Earth at quadrature phase is as high as 25 % in the B band and decreases steadily with wavelength to 8 % in the I band (see Table 3). Similar values were reported from direct satellite measurements of the Earth polarization (Wolstencroft & Breon 2005).

This work provides the most comprehensive measurements of the polarization of the integrated light of the planet Earth up to now. The determined values can be used as benchmark values for tests of polarization models and for predictions for future polarimetric observations of Earth-like extra-solar planets. In particular we describe accurately our measurements and assess the uncertainties. In addition we apply for the first time a polarization efficiency ϵ correction which is based on lunar soil measurements, and which is significantly different from previously used volcanic rock measurements.

Similar to our data of Earth the models of Stam (2008) for horizontally inhomogeneous Earth-like planets with thick liquid water cloud coverage show also a decrease in fractional polarization with wavelength but with a significantly steeper slope. This may indicate that other scattering components, for example aerosols, thin liquid water clouds, and ice clouds contribute significantly to the Earth polarization in the I band (see Karalidi et al. 2012).

Are our polarization values for the planet Earth representative or should we expect large temporal variations? Our data were taken during two observing runs lasting each a few days. Two data sets are from similar phase angles, 73.0° and 75.5° , but they were taken 7 months apart. The measured fractional polarization differs by about $\Delta q/q \approx 0.1$. Also the deviation of the data points from the fit $q_{\text{fit}} = q_{\max} \sin^2 \alpha$ is at the same level $(|q - q_{\text{fit}}|)/q \approx 0.1$. This scatter is at the level of our calibration errors. Therefore, variation of the intrinsic polarization signal of Earth on the 10 % level could be present in our data without being recognized. Our measurements show certainly no changes at the $\Delta q/q \approx 0.3$ level as suggested by Sterzik et al. (2012). Variations in the fractional polarization are of interest because they could be used as diagnostic tool for investigations of surface structures or temporal changes in the cloud coverage of extra-solar planets.

Because our study includes a detailed assessment of the uncertainties for each step in our determination, we can now discuss how the Earth polarization measurement could be improved.

Polarization variability studies could be carried out with enhanced sensitivity selecting observing periods and filters with strong earthshine polarization signals in order to minimize statistical noise and systematic effects in the data extraction. Observations in the B and V filter, and for phase angles in the range from $\alpha = 40^\circ$ to 100° would be ideal for such studies. Measurements taken for several consecutive nights would allow a sensitive search for day to day variation at a level of $\Delta q/q \approx 0.03$ due to variable cloud coverage. Also multiple epoch data could be collected for an investigation of long term and seasonal polarization changes.

The determination of a more accurate wavelength dependence of the earthshine polarization could be established with long integrations for phase angles between $50^\circ - 80^\circ$ when the earthshine polarization signal is strong, the level of scattered light from the moonshine still low, and the time for observations after twilight long enough for observations in multiple filters.

More accurate phase curves require a careful analysis of the data from different phases because the earthshine observing conditions and the associated measuring and calibration procedures change strongly with lunar phase. If these problems can be solved then one could determine accurately the peak in the fractional polarization curve near $\alpha = 90^\circ$ as function of wavelength and investigate the presence of a rainbow feature in the polarization data around $\alpha = 40^\circ$ (see Stam 2008).

A more accurate absolute value for the polarization of the planet Earth requires first more data in order to average out intrinsic variations. Equally important is a more accurate determination of the surface albedo for the measuring region and the associated polarization efficiency $\epsilon(\lambda, a_i)$ for the correction of the lunar back-scattering.

The imaging polarimetry of the earthshine presented in this study and the spectro-polarimetric results from Sterzik et al. (2012) and Takahashi et al. (2013) demonstrate that the investigation of the Earth polarization via earthshine measurements is very useful and attractive. Detailed and versatile investigations

are possible with existing polarimetric instruments as used by Sterzik et al. (2012) and Takahashi et al. (2013) or with small, specific experiments as demonstrated in this work. The obtained results can be compared with model calculations like those described in Stam (2008) and teach us about light scattering processes of planets. Because we know so well our Earth we can also investigate subtle effects, which are potentially important in other planets. Building up our knowledge on scattering polarization from Earth could therefore become also important for the future polarimetric investigation of extra-solar planets.
